Assignment Nr. 1

1.1 Primary Ray-Generation for a Perspective Camera Model

To get to the center of image plane from the origin, we have to move in direction of the viewing direction d : $o + f \cdot d$. To move in y direction in the image plane, the vector is already given as the up-vector u . As the vector in x direction is perpendicular to both d and u , we can construct it by $v = d \times u$. Because u and d are normalized, v is also normalized. To compute how far we have to move in x direction from the center of our image plane for a given coordinate x , we compute $x_{diff} = x - \frac{resX}{2}$. Similar for y direction. In combination, we end up with $d_r = o + f \cdot d + u \cdot (y - \frac{resY}{2}) + v \cdot (x - \frac{resX}{2})$

1.2 Ray-Surface Intersection

a)

As the plane is defined by $(p - n) \cdot a = 0$, in order to check if $r(t)$ is in the plane, we have to find a t such that $(r(t) - n) \cdot a = 0$.

$$\begin{aligned}
 (r(t) - n) \cdot a &= 0 \\
 ((o + t \cdot d) - n) \cdot a &= 0 \\
 (o + t \cdot d) \cdot a - n \cdot a &= 0 \\
 (o + t \cdot d) \cdot a &= n \cdot a \\
 o \cdot a + t \cdot d \cdot a &= n \cdot a \\
 t \cdot d \cdot a &= n \cdot a - o \cdot a \\
 t \cdot d \cdot a &= a \cdot n - o \cdot a \\
 t &= \frac{a \cdot n - o \cdot a}{d \cdot a}
 \end{aligned}$$

This fraction exists if $d \cdot a \neq 0$, or in other words the vector d of the ray is not parallel to the plane.

b)

In order for $r(t)$ to intersect a bounding box, it has to exist an t , such that all coordinates of $r(t)$ are within the boundaries defined by min and max . Looking at the min value of x direction first:

$$\begin{aligned}
 o_x + t_{min_x} \cdot d_x &= x_{min} \\
 \Rightarrow t_{min_x} &= \frac{x_{min} - o_x}{d_x}
 \end{aligned}$$

We see that $t_{min} \geq \frac{x_{min} - o_x}{d_x}$, so that the x coordinate of $r(t)$ can be in our box. If we proceed similar for y, z coordinates, we end up with $t_{min} = \frac{min-o}{d}$, where the division is

the element wise division. The same applied to max results in $t_{max} = \frac{max-o}{d}$.

If $max(t_{min}) > min(t_{max})$, then $r(t)$ doesn't pass through our box, since before the last of our coordinates is within our box, the first of the other coordinates is out of the box again. Otherwise, $r(t)$ passes through our box. The first t where it does so is $max(t_{min})$.

c)

There are several ways to do this, here we show a parametrical check:

$r(t)$ can only pass through the triangle, if it passes through the plane we get if we extend the triangle. We get the normal of the plane by computing $n = (p_2 - p_1) \times (p_3 - p_1)$.

If we set $a = p_3$, we can compute the intersection point p of $r(t)$ and the plane according to 1.2 a). In order to check if p is on the plane, we check there exist α, β such that $p = p_1 + \alpha \cdot (p_2 - p_1) + \beta(p_3 - p_1)$, with $\alpha, \beta \geq 0, \alpha + \beta \leq 1$.
